Multiprocessor Platform

ABSTRACT

In this paper, we focus on splitting a task into multiple sub-tasks to improve schedulability performance for a set of tasks subject to timing constraints. Targeting FPS (Fixed Priority Scheduling) as a scheduling algorithm and RTA (Response Time Analysis) as a schedulability analysis on a multiprocessor platform, we develop a systematic method to utilize the task split, which addresses (i) how to apply the task split without violating the timing requirement of the original tasks and (ii) how to apply each task so as to make an unschedulable task set to be schedulable. Our simulation results demonstrate that RTA with the method finds 16.1%–19.4% (on average) additional task sets that were not proven schedulable by the vanilla RTA.

1. Introduction

Timely execution of a set of tasks is the main focus of real-time systems. To achieve this, numerous studies have paid attention to how to determine the execution order of tasks (called scheduling algorithm) and how to guarantee no deadline miss of tasks before run-time (called schedulability analysis), e.g., [1–5]. However, there is still a room for further schedulability performance improvement (i.e., providing timing guarantees for more task sets), as most schedulability analyses are only sufficient (not necessary). For example, there has been no closed-form exact (i.e., sufficient and necessary) schedulability analysis even for the most fundamental scheduling algorithms such as global FPS (Fixed-Priority Scheduling) and EDF (Earliest Deadline First) on a multiprocessor platform.

In this paper, we develop a simple yet effective way to improve schedulability performance, which splits a task into multiple sub-tasks. While the task split can be generally applicable to most (if not all) existing scheduling algorithms and their schedulability analyses, the main challenges are (CH1) how to apply the task split without violating the timing requirement of the original tasks, and (CH2) how to split each task so as to make an unschedulable task set to be schedulable. Targeting FPS as a scheduling algorithm and RTA (Response Time Analysis) as a schedulability analysis on a multiprocessor platform, we develop a systematic method that addresses CH1 and CH2. Note that there have been some studies that utilize the task split [6–8], which focus on how to efficiently split a task (to be executed in multiple processors while each of other tasks is executed in a designated processor) in order to efficiently occupy each processor in semi-partitioned scheduling. Therefore, they are totally different from the proposed method, which splits multiple tasks in global scheduling.

To verify the effectiveness of the proposed method, we generate a number of task sets for varying number of processors, and compare the number of task sets proven schedulable by the vanilla RTA [3] and that by RTA with the method. Our simulation results show that RTA with the method significantly improves the schedulability performance in all settings; it covers 16.1%–19.4% (on average) additional task sets that were not proven schedulable by the vanilla RTA.

This paper makes the following contributions:

• Developing a systematic method to utilize the task split for schedulability improvement of global multiprocessor scheduling, and

• Applying the method to RTA for FPS, and demonstrating its effectiveness through simulation results.

System model. In this paper, we consider a set of sporadic real-time tasks (denoted by \( r \)), in which each task \( r_i \in r \) is represented by \( T_i \) (the period) and \( C_i' \) (the worst-case execution time). A job of \( r_i \), once released at \( t \), should finish its execution (that amounts to at most \( C_i' \)) until its absolute deadline \( t + T_i \), and the release times of two consecutive jobs of \( r_i \) are separated by at least \( T_i \). Let the length of the quantum be one time unit; all task parameters \( \{ T_i \} \) and \( \{ C_i \} \) are natural numbers. We consider a multiprocessor platform consisting of \( m \) identical processors. We target FPS (Fixed-Priority Scheduling) in which each task has its own pre-defined task-level priority; at any time,

E-mail address: jinkyu.lee@skku.edu.

1 By global scheduling, we mean that a task can be executed in any processor as opposed to partitioned scheduling. From now on, we will omit the term “global” when it is not necessary to refer.

FPS chooses to execute (up to) \( m \) jobs whose invoking tasks’ priorities are the highest. Let \( \mathcal{H}(r) \) denote a set of tasks in \( r \), whose priority is higher than \( r_k \).

### 2. Schedulability improvement via task split

In this section, we target RTA (Response Time Analysis) for FPS on a multiprocessor platform \([3]\), and develop a task split method that improves the schedulability performance of FPS associated with RTA.

The basic structure of RTA for FPS on a multiprocessor platform \([1, 2]\) is as follows. We target an interval of length \( \ell \), which starts from the release time of the job of \( r_k \) of interest. We define \( I_{\text{carry-in}}(\ell) \) as a cumulative length of intervals in which jobs of \( r_k \) execute while the job of \( r_k \) of interest cannot in the target interval of length \( \ell \). Considering the job of \( r_k \) of interest cannot execute only when \( m \) other higher-priority jobs are executed, the following inequality is a sufficient condition for the job of \( r_k \) of interest to be schedulable \([1, 2]\):

\[
\sum_{r_i \in \mathcal{H}(r_k)} \min(I_{\text{carry-in}}(\ell), \ell - C_k + 1) < m \cdot (\ell - C_k + 1) .
\]  

(1)

Then, the remaining step is to upper-bound \( I_{\text{carry-in}}(\ell) \) for all jobs of \( r_k \). By definition, \( I_{\text{carry-in}}(\ell) \) can be upper-bounded by the maximum execution of jobs of \( r_k \) in an interval of length \( \ell \), which is calculated by \( W(\ell) \) \([1, 2]\) as follows.

\[
W(\ell) = E(\ell) \cdot C_k + (C_i \cdot T_i - C_i - S_i - N(\ell) \cdot T_i),
\]  

(2)

where \( N(\ell) = \left\lfloor \frac{\ell - T_i - S_i - N(\ell) \cdot T_i}{C_i} \right\rfloor \). Note that \( S_i \) denotes a slack value of \( r_i \), meaning that every job of \( r_i \) finishes its execution within \( (D_i - S_i) \) from its release; we will explain how to calculate \( S_i \) later.

The calculation of \( W(\ell) \) considers the case where the amount of execution of jobs of \( r_k \) in an interval of length \( \ell \) is maximized as follows. The first job of \( r_i \) starts its execution as late as possible, and the following jobs of \( r_i \) executes as early as possible; in addition, the interval of interest of length \( \ell \) starts when the first job starts its execution. Then, \( N(\ell) \) calculates the number of jobs of \( r_k \) whose deadline is within the interval, each contributing the full execution \( C_i \). On the other hand, the second term of Eq. (2) calculates the amount of execution of the carry-out\(^2\) job of \( r_k \) in the interval of length \( \ell \). Then, if we replace \( I_{\text{carry-in}}(\ell) \) with \( W(\ell) \), Eq. (1) becomes a schedulability analysis for FPS \([1, 2]\).

In \([9]\), it has been revealed that a critical instant of a job of \( r_k \) under FPS on a multiprocessor platform occurs only when there are at most \((m - 1)\) higher-priority carry-in\(^3\) jobs in the interval that starts at the release time of the job of \( r_k \). In the case for a task \( r_i \) not to have any carry-in job in an interval of length \( \ell \), the maximum execution of jobs of \( r_k \) in the interval is calculated by \( E(\ell) \) \([3]\) as follows.

\[
E(\ell) = \left\lfloor \frac{\ell}{T_i} \right\rfloor \cdot C_i + \min \{ C_i, \max(0, \ell - \left\lfloor \frac{\ell}{T_i} \right\rfloor \cdot T_i) \}.
\]  

(3)

which is no larger than \( W(\ell) \). The calculation of \( E(\ell) \) considers the case where every job starts its execution as early as possible, and the interval of interest of length \( \ell \) starts when the first job’s execution starts.

Instead of applying \( W(\ell) \) as an upper bound of \( I_{\text{carry-in}}(\ell) \) in Eq. (1), we can apply \( E(\ell) \) for non-carry-in jobs, yielding a tighter schedulability analysis for FPS as follows.

---

\(^2\) A job is said to be carry-out in an interval, if the job is released before the end of the interval and has remaining execution at the end of the interval.

\(^3\) A job is said to be carry-in in an interval, if the job is released before the beginning of the interval and has remaining execution at the beginning of the interval.

---

Lemma 1 (In \([3]\)). A task set \( r \) is schedulable by FPS on an \( m \)-processor platform, if every \( r_k \in r \) has \( C_k \leq \ell \leq T_k \) that satisfies Eq. (4).

\[
A_k(\ell) + \sum_{r_i \in \mathcal{H}(r_k)} \min(E(\ell), \ell - C_k + 1) < m \cdot (\ell - C_k + 1),
\]  

(4)

where \( A_k(\ell) \) is the sum of \((m - 1)\) largest \((W(\ell), \ell - C_k + 1) - (E(\ell), \ell - C_k + 1)\) among \( r_k \in \mathcal{H}(r_k) \).

Proof. In order to apply at most \((m - 1)\) higher-priority carry-in jobs for the critical instant of FPS on a multiprocessor platform, we add the interference as \(\min(E(\ell), \ell - C_k + 1)\) for each higher-priority, and then add the difference between \(\min(W(\ell), \ell - C_k + 1)\) and \(\min(E(\ell), \ell - C_k + 1)\) for \((m - 1)\) higher-priority tasks whose difference is the largest. Then, for any combination of at most \((m - 1)\) higher-priority carry-in tasks, the amount of interference is upper-bounded by the LHS of Eq. (4), which is derived by the condition of the critical instant of FPS on a multiprocessor platform and the meaning of \(W(\ell)\) and \(E(\ell)\). The detailed proof is given in \([3]\). \(\square\)

Then, RTA for FPS operates as follows \([1]\). Initially, \( S_i \) for every task is set to zero. Then, Eq. (4) is checked from the highest-priority task to the lowest-priority task. If a task \( r_k \) is schedulable (i.e., Eq. (4) holds), we calculate an upper bound of the response time of \( r_k \) (denoted by \( R_k \)), which is the sum of \( C_k \) and the LHS (left-hand-side) of Eq. (4) divided by \( m \); also, if \( R_k < T_k \) holds, we set \( S_k \) to \( (T_k - R_k) \). Finally, the task set \( r \) is deemed schedulable, if Eq. (4) holds for every task. Otherwise, we repeat the whole process with update slack values \((S_k)\); the repetition ends with the task set deemed schedulable, or with no more slack update (yielding the task set deemed unschedulable).

The problem to be solved in this paper is as follows. For given \( (r_k \in r) \) and their priorities for FPS, we find how to split each task \( r_k \in r \) into \( r_k' \in r' \), which satisfies the following statement: if we schedule \( (r_k' \in r') \) according to FPS with their original task priorities, RTA for FPS guarantees that there is no job deadline miss of \((r_k' \in r')\), meaning that no job deadline miss of \((r_k \in r)\) if we apply the schedule for \((r_k' \in r')\).

We outline the proposed method for the problem as follows. First, we exemplify how Eq. (4) in RTA for FPS is changed if we split tasks, giving an intuition for the task split (in Example 1). Second, we develop how to split each task even when its parameters are not a multiple of the quantum. Third, we derive a relationship between the schedulability of the original task set and that of the split task set (in Theorem 1). Finally, we develop a systematic way to split all tasks in the target task set in order to make the set schedulable (in Algorithm 1).

Now, we investigate how the task split (also known as the period transformation \([10]\)) impacts on the schedulability of each task set. As a first step, we define a split factor of \( r_k \) as a natural number \( a_k \). That is, \( a_k \) transforms \( r_k \) to \( r_k' \) in which the period and the worst-case execution time of \( r_k ' \) will be divided by \( a_k \); therefore, \( a_k = 1 \) means no task split. For example, \( r_k (T_k = 8, C_k = 4) \) will be transformed into \( r_k' (T_k' = 4, C_k' = 2) \) by \( a_k = 2 \); it is easily checked that the timing guarantee of \( r_k' \) is a multiple of the original task \( r_k \). We will explain how to divide the parameters by \( a_k \), if they are not a multiple of \( a_k \). The following example explains how Eq. (4) changes if we split tasks.

Example 1. Consider a set of three tasks \( r_1 (T_1 = 8, C_1 = 4) \), \( r_2 (8, 4) \) and \( r_3 (12, 6) \) on a two-processor platform. \( r_1 \) and \( r_2 \) have the highest and the lowest priority, respectively.

Since \( E(12) = E(12) = 8 \) and \( \min(E(12), 12 - 6 + 1) = \min(E(12), 12 - 6 + 1) = 7 \) hold, the LHS of Eq. (4) is the same as the RHS (right-hand-side); therefore, \( r_3 \) cannot satisfy Eq. (4).

---

4 How to efficiently find \( \ell \) that satisfies the inequality is explained in \([1]\), which is the same as that for the response time calculation on a uniprocessor platform.
On the other hand, suppose that we split \( r_1 \) and \( r_2 \) by two (i.e., \( a_1 = 2 \) and \( a_2 = 2 \)), yielding \( r'_1(T'_1 = 4, C'_1 = 2) \) and \( r'_2(4, 2) \). Since \( E'_1(12) = E'_2(12) = 6 \) and \( \min(E_1(12), 12 - 6 + 1) = \min(E_2(12), 12 - 6 + 1) = 6 \) hold, the LHS of Eq. (4) is strictly smaller than the RHS; therefore, \( r_2 \) satisfies Eq. (4).

As shown in the example, a task split of \( r_i \) can reduce interference of \( r_i \) to other tasks; this is because, \( E_i(\ell') \) and \( W_i(\ell') \) decrease or remain the same, if we divide \( T_i \) and \( C_i \) by the same natural number larger than 1. On the other hand, a task split of \( r_i \) is not favourable to the schedulability of \( r_i \) (Lines 5–11), and return schedulable with \( \mathcal{S} \). Initially, not affect the priority of \( r_i \) by Algorithm 1. Note that the priority of \( r_i \) is not a multiple of the quantum, and \( \mathcal{CH}(2) \) how to set \( a_i \) for every task to make \( r \) schedulable.

For CH1, we apply the sustainability property \([11]\), which holds for every \( r_i \) in \( \mathcal{S} \). From Example 1, we can utilize the properties of the task split of \( r_i \). Therefore, we need to increase \( \alpha_i \) as much as possible by considering \( r_i \) helps to reduce the interference of \( r_i \) to other tasks; this is because, the ratio between \( \tau_i \) itself; this is because, the ratio between \( \tau_i \) is not decided by the task split of \( r_i \), meaning that the change of

\[
\text{Algorithm 1 Assignment of the task split factor } \{a_i\}
\]

1: For every \( r'_i \in r' \), \( a_i \leftarrow 1 \).
2: UPDATED \( \leftarrow \) True
3: for \( r'_i \in r' \) do
4: UPDATED \( \leftarrow \) False
5: for every \( r'_i \in r' \) do
6: if Eq. (4) holds for \( r'_i \) then
7: SCHE \( = \) True
8: else
9: SCHE \( = \) False
10: end if
11: end for
12: if SCHE = True holds for every \( r'_i \in r' \) then
13: Return schedulable with \( \{a_i\} \)
14: end if
15: for every \( r'_i \in r' \) do
16: Find the largest \( a'_i \in [1, \text{max}_i] \) that satisfies Eq. (4) for \( r'_i \)
17: if \( a'_i > a_i \) then
18: \( a_i \leftarrow a'_i \)
19: UPDATED \( \leftarrow \) True
20: end if
21: end for
22: end for
23: Return unschedulable

Lines 15–21 can be repeated up to \( n \cdot \text{max}_i \) times, the time-complexity of Algorithm 1 is \( O(n^2 \cdot \text{max}_i, T_i \cdot \text{max}_i) \). Since we can perform Algorithm 1 offline, the time-complexity is affordable.

\section{Evaluation}

In this section, we evaluate the effectiveness of the task split method in finding additional schedulable task sets.

\textbf{Task set generation.} We have two parameters for task set generation: (i) the number of processors (i.e., \( m = 2, 4, 8, \) and 16), and (ii) the distribution of task utilization \( C_i/T_i \) (i.e., the bimodal distribution with parameters 0.1, 0.3, 0.5, 0.7 and 0.9, and the exponential distribution with the same parameters). For every combination of (i) and (ii), we randomly generate 1000 task sets based on the set generation method in [1,12], yielding 40,000 task sets in total. In each task set, the number of tasks is at least \( m + 1 \), and the task set utilization \( \sum C_i/T_i \) is at most \( m \). To effectively apply the task split factor \( i \leq a_i \leq 6 \), we set \( T_i \) and \( C_i \) as a multiple of 60.

\textbf{Evaluation settings.} For each task's priority under FPS, we considered two representative priority assignment policies, known to be effective to a multiprocessor platform: (i) the rate monotonic algorithm.
assigns a higher priority to a smaller period \(T_s\), and (ii) the \((T_s - C)\) monotonic algorithm (denoted by TCM) that assigns a higher priority to a smaller \((T_s - C)\) \([14]\). For the schedulability analysis, we compare the vanilla RTA (i.e., \(\text{Lemma 1, denoted by RTA}\)), to the RTA with the task split (i.e., \(\text{Theorem 1 in which } a)\) is assigned by Algorithm 1, denoted by RTA\(T^S\)). For the generated task sets, we count the number of task sets deemed schedulable by the following pairs of a priority assignment of FPS and a schedulability analysis: RM-RTA, RM-RTA\(T^S\), TCM-RTA and TCM-RTA\(T^S\).

### Performance in covering schedulable task sets

We make the following three important observations. First, the proposed task split method significantly improves the schedulability performance. As shown in Fig. 1, for every pair of the priority assignment policy of FPS and the number of processors, RTA\(T^S\) finds 16.1%–19.4% additional schedulable task sets, compared to RTA. This indicates the proposed task split method is very effective in covering schedulable task sets, achieving the goal of this paper.

Second, the proposed task split method is effective to both RM and TCM. If we focus on the evaluation results of Fig. 1(a) and those of Fig. 1(b), the schedulability performance improvement of RTA\(T^S\) over RTA is 16.1%–17.1% and 16.3%–19.4%, respectively for RM and TCM. Hence, the proposed task split method is robust to the priority assignment policy of FPS.

Third, the schedulability performance improvement by the proposed method varies with the task utilization distribution, and there exists a tendency that the method is more effective to task sets in each of which the number of tasks is sufficiently large. As shown in Table 1 for the case of \(m = 8\), the exponential distribution with 0.1 and that with 0.3, which result in the largest average number of tasks in each task set (i.e., 44.1 and 20.0, respectively), yield 18.4%–23.6% schedulability improvement. On the other hand, the binomial distribution with 0.9 and that with 0.7, which result in the smallest average number (i.e., 10.2 and 11.1, respectively) yield only 5.0%–14.9% schedulability improvement. This is because, if a task set consists of only a few tasks, the number of tasks which can reduce interference to the target task (that is unschedulable without the task split method) is small, disallowing the target task to be schedulable by the task split. Note that we observe a similar trend to other \(m\).

| Table 1 |
|-----------------|-------------------|-------------------|
| **The number of task sets found schedulable by X-RTA\(T^S\), divided by that by X-RTA, for \(m = 8\) under different task utilization distributions, where X is RM or TCM.** |
| **Task utilization distribution** | **RM-RTA\(T^S\)** | **TCM-RTA\(T^S\)** |
| Binomial with 0.1 (17.7) | 123.2% | 121.4% |
| Binomial with 0.3 (14.6) | 115.3% | 115.7% |
| Binomial with 0.5 (12.7) | 114.4% | 114.1% |
| Binomial with 0.7 (11.1) | 114.5% | 114.3% |
| Binomial with 0.9 (10.2) | 114.9% | 105.0% |
| Exp. with 0.1 (44.1) | 123.6% | 119.2% |
| Exp. with 0.3 (20.0) | 118.4% | 120.0% |
| Exp. with 0.5 (16.4) | 113.8% | 114.7% |
| Exp. with 0.7 (14.9) | 111.8% | 116.7% |
| Exp. with 0.9 (14.6) | 112.9% | 116.5% |
| **All distributions (17.6)** | 117.1% | 116.6% |

4. Conclusion

In this paper, we developed a systematic method of how to improve schedulability performance via the task split. We demonstrated that the method finds 16.1%–19.4% (on average) additional schedulable task sets. In the future, we would like to efficiently generalize the method to constrained-deadline tasks in which the relative deadline is the same as or smaller than the period.
